DESCRIPTION: The purpose of this Clinical Practice Update Expert Review is to provide clinicians with guidance on the diagnosis and management of atrophic gastritis, a common preneoplastic condition of the stomach, with a primary focus on atrophic gastritis due to chronic Helicobacter pylori infection—the most common etiology—or due to autoimmunity. To date, clinical guidance for best practices related to the diagnosis and management of atrophic gastritis remains very limited in the United States, which leads to poor recognition of this preneoplastic condition and suboptimal risk stratification. In addition, there is heterogeneity in the definitions of atrophic gastritis, autoimmune gastritis, pernicious anemia, and gastric neoplasia in the literature, which has led to confusion in clinical practice and research. Accordingly, the primary objective of this Clinical Practice Update is to provide clinicians with a framework for the diagnosis and management of atrophic gastritis. By focusing on atrophic gastritis, this Clinical Practice Update is intended to complement the 2020 American Gastroenterological Association Institute guidelines on the management of gastric intestinal metaplasia. These recent guidelines did not specifically discuss the diagnosis and management of atrophic gastritis. Providers should recognize, however, that a diagnosis of intestinal metaplasia on gastric histopathology implies the diagnosis of atrophic gastritis because intestinal metaplasia occurs in underlying atrophic mucosa, although this is often not distinctly noted on histopathologic reports. Nevertheless, atrophic gastritis represents an important stage with distinct histopathologic alterations in the multistep cascade of gastric cancer pathogenesis.

METHODS: The Best Practice Advice statements presented herein were developed from a combination of available evidence from published literature and consensus-based expert opinion. No formal rating of the strength or quality of the evidence was carried out. These statements are meant to provide practical advice to clinicians practicing in the United States.

BEST PRACTICE ADVICE STATEMENTS

BEST PRACTICE ADVICE 1: Atrophic gastritis is defined as the loss of gastric glands, with or without metaplasia, in the setting of chronic inflammation mainly due to Helicobacter pylori infection or autoimmunity. Regardless of the etiology, the diagnosis of atrophic gastritis should be confirmed by histopathology. BEST PRACTICE ADVICE 2: Providers should be aware that the presence of intestinal metaplasia on gastric histology almost invariably implies the diagnosis of atrophic gastritis. There should be a coordinated effort between gastroenterologists and pathologists to improve the consistency of documenting the extent and severity of atrophic gastritis, particularly if marked atrophy is present. BEST PRACTICE ADVICE 3: Providers should recognize typical endoscopic features of atrophic gastritis, which include pale appearance of gastric mucosa, increased visibility of vasculature due to thinning of the gastric mucosa, and loss of gastric folds, and, if with concomitant intestinal metaplasia, light blue crests and white opaque fields. Because these mucosal changes are often subtle, techniques to optimize evaluation of the gastric mucosa should be performed. BEST PRACTICE ADVICE 4: When endoscopic features of atrophic gastritis are present, providers should assess the extent endoscopically. Providers should obtain biopsies from the suspected atrophic/metaplastic areas for histopathological confirmation and risk stratification; at a minimum, biopsies from the body and antrum/incisura should be obtained and placed in separately labeled jars. Targeted biopsies should additionally be obtained from any other mucosal abnormalities. BEST PRACTICE ADVICE 5: In patients with histology compatible with autoimmune gastritis, providers should consider checking antiparietal cell antibodies and anti-intrinsic factor antibodies to assist with the diagnosis. Providers should also evaluate for anemia due to vitamin B-12 and iron deficiencies. BEST PRACTICE ADVICE 6: All individuals with atrophic gastritis should be assessed for H pylori infection. If positive, treatment of H pylori should be administered and successful eradication should be confirmed using non-serological testing modalities. BEST PRACTICE ADVICE 7: The optimal endoscopic surveillance interval for patients with atrophic gastritis is not well-defined and should be decided based on individual risk assessment and shared decision making. A surveillance endoscopy every 3 years should be considered in individuals with advanced atrophic gastritis, defined based on anatomic extent and histologic grade. BEST PRACTICE ADVICE 8: The optimal surveillance interval for individuals with autoimmune gastritis is unclear. Interval endoscopic surveillance should be considered based on individualized assessment and shared decision making. BEST PRACTICE ADVICE 9: Providers should recognize pernicious anemia as a late-stage manifestation of autoimmune gastritis that is characterized by vitamin B-12 deficiency and macrocytic anemia. Patients with a new diagnosis of pernicious anemia who have not had a recent endoscopy should undergo endoscopy with topographical biopsies to confirm corpus-predominant atrophic gastritis for risk stratification and to rule out prevalent gastric neoplasia, including neuroendocrine tumors. BEST PRACTICE ADVICE 10: Individuals with autoimmune gastritis...
should be screened for type 1 gastric neuroendocrine tumors with upper endoscopy. Small neuroendocrine tumors should be removed endoscopically, followed by surveillance endoscopy every 1–2 years, depending on the burden of neuroendocrine tumors. **BEST PRACTICE ADVICE 11:** Providers should evaluate for iron and vitamin B-12 deficiencies in patients with atrophic gastritis irrespective of etiology, especially if corpus-predominant. Likewise, in patients with unexplained iron or vitamin B-12 deficiency, atrophic gastritis should be considered in the differential diagnosis and appropriate diagnostic evaluation pursued. **BEST PRACTICE ADVICE 12:** In patients with autoimmune gastritis, providers should recognize that concomitant autoimmune disorders, particularly autoimmune thyroid disease, are common. Screening for autoimmune thyroid disease should be performed.

**Keywords:** Gastric Cancer; Gastric Intestinal Metaplasia; *Helicobacter pylori*; Screening; Surveillance; Early Cancer Detection; Endoscopy; Best Practice; Atrophic Gastritis.

Atrophic gastritis (AG) is a preneoplastic condition defined by replacement of appropriate gastric glandular structures with connective tissue (nonmetaplastic atrophy) or a different, non-native epithelium (metaplastic atrophy) on a background of chronic inflammation. AG is considered the first of a multistep precancerous cascade, with more advanced stages including gastric intestinal metaplasia (IM), dysplasia, and ultimately gastric adenocarcinoma. The 2 most common etiologies of AG are chronic infection with *Helicobacter pylori* and autoimmunity, with the former recognized as the dominant etiology. It is important for providers to recognize the broad spectrum of clinical manifestations of AG, which includes both gastric and extragastric manifestations.

**Epidemiology**

The estimated prevalence of AG is up to 15% in US populations, and may be greater in specific populations with a higher baseline prevalence of *H pylori* or incidence of gastric adenocarcinoma, such as non-White racial/ethnic minority groups and early-generation immigrants from high-risk countries. AG is typically asymptomatic and may go undiagnosed, or with nonspecific symptoms that may occur later in the course. In addition, the inconsistent reporting of AG on histopathology contributes to the underdiagnosis of this condition. Based on a meta-analysis, the rate ratio of AG incidence in patients with vs without *H pylori* infection was 5.0 (95% confidence interval, 3.1–8.3) and AG incidence was very low (<1% annually) among *H pylori*-uninfected individuals, supporting the strong relationship between *H pylori* and AG. Other risk factors for nonautoimmune AG include age, tobacco use, high-salt diet, and possibly chronic bile acid reflux.

Autoimmune gastritis (AIG) is significantly less common than *H pylori*-associated AG (HpAG). The prevalence has been estimated to approximate 0.5%–2%, although this might be an overestimation. The prevalence increases with age and the presence of other autoimmune diseases (eg, autoimmune thyroid diseases and type 1 diabetes mellitus). For example, it is estimated that up to one-third of patients with autoimmune thyroid disease have AIG. Women have a higher prevalence of AIG compared to men. In marked contrast to HpAG, racial and ethnic variation is not prominent in AIG. Pernicious anemia (PA)—a late-stage complication of AIG characterized by megaloblastic anemia due to vitamin B-12 deficiency—is even rarer, with an estimated prevalence of 0.15%–1.18,21

**Natural History of Atrophic Gastritis as a Preneoplastic Condition**

The estimates for the risk of progression from AG to high-grade dysplasia or gastric adenocarcinoma vary widely and reflect the heterogeneity of study populations and study design. It is estimated that the risk of progression of AG to gastric adenocarcinoma ranges from 0.1% to 0.3% per year (similar to the estimated rate of malignant progression from nondysplastic Barrett’s esophagus or low-risk colorectal adenomas), but may be higher, depending on AG severity, extent, concomitant IM, and other factors. As a late-stage manifestation of AIG, the diagnosis of PA identifies patients who have had corpus-predominant AG for at least several years. One meta-analysis of 27 studies demonstrated a nearly 7-fold significantly higher relative risk of gastric cancer in patients with vs without PA; although most individual studies suggest a 2- to 4-fold higher risk.

Patients with chronic AG, particularly AIG given the corpus-predominant atrophy, are also at increased risk of type I NETs. These tumors develop as a consequence of the parietal cell loss, which leads to reduced gastric acid secretion and downstream persistent hypergastrinemia, enterochromaffin-like cell (ECL) hyperplasia, and, in a small percentage, ECL dysplasia and gastric NETs. Based on longitudinal cohort studies, the incidence rate of type I gastric NETs in patients with chronic AG is estimated as 0.4–0.7% per year, with variability across the literature.

**Histopathologic Features of Atrophic Gastritis**

The pathogenesis of AG involves the interaction between environmental and genetic determinants to a varying extent depending on the primary trigger, namely *H pylori* infection vs autoimmunity. In some individuals, chronic *H pylori* gastritis can advance to atrophy (loss of gastric glands) with or without replacement by metaplastic epithelium. In AIG, autoantibodies against parietal cells and intrinsic factor along with T-cell–mediated destruction of the gastric

**Abbreviations used in this paper:** AG, atrophic gastritis; AIG, autoimmune gastritis; BPA, Best Practice Advice; ECL, enterochromaffin-like; ESGE, European Society of Gastrointestinal Endoscopy; HD-WLE, high-definition white-light endoscopy; HpAG, *Helicobacter pylori*-associated atrophic gastritis; IFA, intrinsic factor antibody; IM, intestinal metaplasia; LBC, light blue crest; NBI, narrow-band imaging; OLGAS, Operative Link for Gastritis Assessment; OLGIM, Operative Link for Gastric Intestinal Metaplasia Assessment; PA, pernicious anemia; PCA, parietal cell antibody; PG, peptic ulcer disease; PPI, proton pump inhibitor; TLE, traditional light endoscopy; UC, ulcerative colitis
oxymet mucosa leads to the characteristic pattern of corpus-dominant atrophy with antral sparing that distinguishes AIG from HpAG. That said, overlap exists between these phenotypes, both related to pathogenesis (eg, molecular mimicry between \textit{H pylori} antigens and the gastric \(H^+\)/\(K^+\) ATPase has been proposed as a trigger for AIG\cite{19,32} and clinical considerations.\cite{19} Regardless of the etiology, the diagnosis of AG should be confirmed by histopathology (Figure 1A–H) (Best Practice Advice [BPA] 1).

AG is a slow process, in which, after years of mucosal inflammation, gastric glands gradually decrease in size and may disappear completely. The glands may be replaced with connective tissue (nonmetaplastic atrophy, usually referred to as atrophy) or with a different type of epithelium (metaplastic atrophy, ie, IM or pseudopyloric metaplasia). IM is the most frequently diagnosed histopathologic manifestation of AG.

In HpAG, atrophic changes arise initially in the incisura and the antrectoral transitional mucosa as small foci with loss of glands and IM. Over time, these foci coalesce to form larger patches of atrophic/metaplastic mucosa along the lesser curvature and the antrum, and eventually spread to the corpus/fundus, followed by the loss of gastric acidity. In AIG, the typical histologic manifestation is corpus-dominant AG, with destruction of individual oxyntic glands by lymphocytes.\cite{34} In both conditions, there may be progressive loss of oxyntic glands, and increasingly prominent pseudopyloric and IM. ECL hyperplasia and type 1 gastric NETs can develop, indicating a state of hypergastrinemia.\cite{34,35} If antral atrophy is seen in AIG, concomitant HpAG should be considered. If the anatomic location of the biopsies is uncertain, special stains (eg, gastrin [antrum], pepsinogen I [corpus]) may discriminate between antral mucosa and pseudopyloric metaplasia, which can be avoided if the biopsy specimens from the corpus and antrum/incisura are placed in separate specimen jars following the updated Sydney protocol (discussed below).

In clinical practice, the ability to report AG depends on presentation of antral and corpus biopsy specimens in separate jars, and correct orientation of the specimens during the paraffin-embedding process. Of note, gastric IM is readily identified irrespective of mucosal thickness of the biopsy specimen and orientation.

Severity and topographic distribution of atrophic lesions are well-established determinants of gastric cancer risk. These prognosticators are incorporated in 2 classification systems for risk assessment: Operative Link for Gastritis Assessment (OLGA) and Operative Link for Gastric Intestinal Metaplasia Assessment (OLGIM) (see Supplementary Figure 1A and B for details).\cite{36,37} Both OLGA and OLGIM are advocated by international guidelines for risk stratification of individuals diagnosed with precancerous gastric mucosal changes\cite{38,39}; however, reporting of OLGA/OLGIM stage has not gained a foothold in clinical practice in the United States. Barriers to routine incorporation in practice should be identified and addressed. At the very least, providers should be aware that the presence of IM on gastric histology almost invariably implies the diagnosis of AG, and the presence of extensive atrophy and metaplasia are associated with an increased cancer risk.\cite{40} There should be a coordinated effort between gastroenterologists and pathologists to improve the consistency of documenting AG severity and extent, particularly if marked atrophy is present (BPA 2).

**Diagnostic Workup**

*Endoscopic Evaluation for Atrophic Gastritis*

The endoscopic appearance of AG may be subtle. Endoscopists should perform a high-quality examination following a systematic approach in order to maximize diagnostic yield. First, endoscopists should ensure excellent mucosal visualization, which necessitates adequate air insufflation and mucosal cleansing, and should spend sufficient time carefully examining the gastric mucosa.\cite{51,52} Defoaming and mucolytic agents, such as simethicone and 1 % N-acetylcysteine, may be considered because water irrigation alone may be insufficient for mucosal washing.\cite{53,54} The entire gastric lumen should be examined for the overall appearance of the mucosa, including the color and texture, appearance of submucosal blood vessels, and the architecture of the gastric rugae, followed by targeted examinations of focal abnormalities using high-definition white-light endoscopy (HD-WLE) or image-enhanced techniques, such as narrow-band imaging (NBI). Photographic documentation should be obtained to cover the cardia and fundus, lesser and greater curvature of corpus and antrum, incisura angularis, and pylorus (Figure 2).

Providers should recognize that HpAG and AIG have different patterns of gastric mucosa involvement. In the former, the atrophy typically initiates in the gastric antrum and expands proximally, and may involve the entire stomach in severe cases. In 1969, Kimura and Takemoto proposed a classification system for AG based on the extent of the atrophic border.\cite{16} In this system, gastric atrophy is categorized as closed (C) or open (O) type, each with a grade based on the extent of atrophic border (Supplementary Figure 2). Multiple reports have consistently demonstrated that severe or extensive atrophy (O2–O3 types) has significantly higher cumulative risk of gastric cancer compared with mild atrophy (C1–C2 types)\cite{57,49}; these findings are concordant with those based on OLGA/OLGIM systems described above. In AIG, because of the destruction of parietal cells by autoantibodies, the areas of atrophy primarily involve the gastric corpus and fundus with characteristic sparing of the antrum. In the early phase of the AIG, the mucosal changes are usually subtle except for nonspecific erythema, and the diagnosis of AIG can be missed without taking biopsies.\cite{17} With progressive loss of parietal cells, the mucosa of the entire gastric body appears atrophic.

Compared to conventional WLE, HD-WLE offers significantly improved sensitivity for identifying premalignant mucosal changes (Figure 2).\cite{50,51,52} Atrophic mucosa typically has a pale appearance, with increased visibility of submucosal blood vessels due to thinning of the gastric mucosa and loss of gastric folds (BPA 3). Frequently, a border of atrophic mucosa can be identified (Figure 2).
study, the sensitivity and specificity of absence of rugal folds for moderate to severe AG in the gastric corpus were 67% and 85%, respectively. A combination of magnifying endoscopy and chromoendoscopy or image-enhanced techniques (eg, NBI) provides more detailed evaluation of gastric mucosa and microvascular architecture. Although magnifying endoscopy is not routinely available in the United States, the near-focus function of the newer-generation HD endoscopes, which are available in the United States, does provide better differentiation of mucosal abnormalities compared to the older-generation HD-WLE (Figure 2).

Because IM is an indicator of AG, providers should similarly be able to recognize endoscopic features of IM (BPA 3). Compared to AG, IM can be more reliably identified using HD-WLE, with the sensitivity further improved with image-enhancing technology, such as NBI. Relevant to US practice, prospective multicenter study using HD-WLE with NBI showed a sensitivity and specificity of 87% and 97% for the diagnosis of IM and 92% and 99% for the diagnosis of dysplasia, even without using magnifying endoscopy. On HD-WLE, the areas with IM typically appear mildly nodular with ridged or tubulovillous mucosal patterns. The “light blue crest” (LBC) sign, defined as fine, blue-white lines on the crests of the epithelial surface (Figure 2G), is characteristic for IM, with sensitivity and specificity approximately 90%, and positive and negative likelihood ratio 8.98 and 0.12, respectively, based on one

Figure 1. Histopathologic features of normal gastric mucosa, chronic AG, and gastric NET. (A) Normal gastric oxyntic mucosa, characterized by short foveolae (pits) and tightly packed, straight glands. The glands are primarily lined by parietal (pink) cells, which predominate in the upper two-thirds, and by chief (purple) cells at the base. (B) Normal antral mucosa, with wider foveolae and loosely packed glands, primarily lined by mucus-secreting cells. (C, D) H pylori–associated AG. (C) Corpus mucosa with chronic inflammation, moderate loss of oxyntic glands, pseudopyloric metaplasia (asterisks), and IM (thick arrow). Remaining parietal cells (thin arrows) are forming short, disorganized glands. In marked oxyntic atrophy (not shown), there may be complete absence of parietal and chief cells, making the histologic findings indistinguishable from those of antral atrophy. (D) Antral mucosa with shrunk, vanishing glands (thin arrows) and foci of IM (thick arrows) surrounded by fibromuscular tissue in the lamina propria. (E, F) Oxyntic mucosa showing fully developed autoimmune gastritis. (E) Complete absence of parietal and chief cells replaced by pseudopyloric (asterisks) and intestinal (arrow) metaplasia, in a background of chronic inflammation. In this case, glands with pseudopyloric metaplasia show ECL cell hyperplasia, highlighted in (F) with chromogranin A stain. Linear (thin arrow) and micronodular (thick arrow) ECL cell hyperplasia are observed. In earlier stages of autoimmune gastritis, the destruction of oxyntic glands by infiltrating lymphocytes (not shown) and the corpus-predominant pattern of inflammatory and atrophic changes strongly suggests this condition. (G, H) Gastric type 1 ECL cell NET. (G) The tumor is composed of well-differentiated cells with monomorphic round nuclei, arranged in small nests (arrows) infiltrating the lamina propria. The neuroendocrine differentiation is confirmed using chromogranin A stain (H).
The so-called white opaque fields (or “white opaque substance”) (Figure 2D), which is the result of microscopic lipid droplets that accumulate in the mucosa of gastric tumors and IM, is also a useful marker for IM, with high specificity (100%; 95% confidence interval, 85%–100%) and limited sensitivity (50%; 95% confidence interval, 40%–50%) in 1 study.60

**Biopsy Protocol**

In the United States, the diagnosis of AG requires histopathologic confirmation. Because of the higher risk in patients with extensive AG vs AG limited to the antrum, providers should follow the updated Sydney protocol for obtaining topographical biopsies.4 This protocol has close to 100% sensitivity in identifying H pylori colonization as well.61 The protocol requires 5 gastric biopsies, which should be placed in separately labeled jars: 2 from the antrum along the lesser and greater curvature, within 2–3 cm of the pylorus; 2 from the gastric corpus (including 1 from the lesser curvature at 4 cm proximal to the incisura angularis and the other from the middle portion of the greater curvature of the gastric body at 8 cm from the cardia), and 1 from the incisura angularis. Because AG/IM frequently involves the incisura angularis, providers should not skip this site when obtaining biopsies.62–64 If the cost incurred by separating each of these sites is a concern, at a minimum the biopsies should be placed in 2 separate specimen jars labeled antrum/incisura and body. Targeted biopsies should be obtained from any visible mucosal abnormalities and placed in appropriately labeled specimen jars (BPA 4).

**Serologic Diagnosis**

Serum pepsinogens (PGs) reflect both the functional and morphologic status of the gastric mucosa and are useful markers of extensive atrophy.65 Chief and mucous neck cells
in the gastric corpus and fundic glands secrete both PG I and PG II, while PG II (but not PG I) is also produced by pyloric glands and Brunner’s glands. At least in regions with high gastric cancer incidence (with most studies from East Asia), PG I levels (<70 μg/L) and low PG I:II ratio (<3.0) demonstrate a high sensitivity and specificity for severe corpus atrophy.66 However, PG testing is not available for routine clinical use in the United States.

In patients with histology compatible with AIG, providers should check parietal cell antibodies (PCAs) and intrinsic factor antibodies (IFA) to assist with the diagnosis (BPA 5). PCA is the most sensitive serum biomarker for AIG, but false positives are not uncommon, as PCA can be elevated in H pylori infection and other autoimmune diseases.19,67 IFA has low sensitivity (<30% in many studies) but high specificity, and is more often positive later in the disease course.32,68 Autoantibody positivity might also predate clinical presentation of AIG, particularly in individuals with other autoimmune disorders.19,69

Management

Test and Treat for Helicobacter pylori

The vast majority of patients with AG have evidence of current or prior infection of H pylori.20,71 Irrespective of etiology, patients with AG should be tested for H pylori and, if positive, H pylori should be eradicated. Subsequent non-serologic H pylori testing should be performed to confirm successful eradication (BPA 6). Normal gastric mucosa may be restored over time in some patients with AG after successful H pylori eradication;72 although most patients may have passed a “point-of-no-return” in which the gastric mucosal damage cannot be reversed despite H pylori eradication.73 For these patients, their risk remains elevated, particularly among those with extensive or moderate to severe atrophy (eg, OLGA/OLGIM III/IV), providing the clinical rationale for endoscopic surveillance even after successful H pylori eradication, a practice supported by international guidelines (Supplementary Table 1). Nevertheless, despite persistent signs of AG, H pylori eradication does still appear to reduce the risk of gastric cancer.74

Endoscopic Surveillance of Atrophic Gastritis

Overall, only a small minority of patients with AG will have neoplastic complications. There is a lack of prospective, randomized controlled trials to support the benefits of performing routine surveillance endoscopy for patients with AG, namely reduced gastric cancer-related morbidity and mortality. However, multiple observational studies consistently demonstrate a strong association between severe AG (based on histology, anatomic distribution, or OLGA/OLGIM III/IV stages) and increased risk of gastric adenocarcinoma; this provides the justification for endoscopic surveillance for these patients to increase the likelihood of detection of gastric cancer at an early stage when resection with curative intent is possible.37,75–79 In addition to risk stratification for gastric neoplasia, endoscopic surveillance in patients with AG should also consider comorbidities, as well as patient values and priorities.80,81 Providers should consider performing endoscopic surveillance every 3 years in patients with advanced AG. However, it should be recognized that optimal surveillance intervals remain to be determined, and shorter or longer intervals may be appropriate depending on individual risk assessment (BPA 7). An algorithm for clinical management of AG is shown in Figure 3.

Additional risk factors that should be considered for informing surveillance intervals include the quality of baseline endoscopy, family history of gastric cancer, immigration history from geographic regions with high incidence of gastric cancer, persistent H pylori infection, smoking history and dietary factors, among others.80,82 This risk stratification-based approach is overall consistent with current guidelines from different professional societies on surveillance for chronic AG and GIM (Supplementary Table 1).

The optimal surveillance strategy for individuals with AIG is unclear (BPA 8). The current European Society for Gastrointestinal Endoscopy guidelines advocate performing surveillance endoscopy at 3–5 years in patients with AIG.73 In patients with PA, observational studies suggest that the risk of gastric adenocarcinoma might be highest within the first year of diagnosis. Reflective of this, the American Society of Gastrointestinal Endoscopy advocates that an upper endoscopy be performed within 6 months of the diagnosis of PA.83 The development of upper gastrointestinal symptoms in patients with PA should also prompt diagnostic endoscopy (BPA 9).

Management of Gastric Neuroendocrine Tumors

Gastric NETs associated with AG represent approximately 80%–90% of all gastric NETs and are overwhelmingly categorized as type 1.84 Small NETs are typically asymptomatic and often diagnosed incidentally. These usually appear as small to tiny nodules <10 mm and are most often found at the gastric corpus or fundus; they are typically well-differentiated with an indolent course.85–88 Endoscopically, they present as polypoid lesions in slight yellow or red color on HD-WLE (Figure 2H–I). The prognosis is determined by the size, depth of invasion, and mitotic activity of the tumor. The rate of metastasis is <10% in gastric NETs ≤2 cm but approaches 20% in NETs >2 cm.89 Small gastric NETs <1 cm are generally amenable to endoscopic resection. The optimal interval for endoscopic surveillance has not been well defined. Providers should resect all small NETs <1 cm endoscopically, and should consider surveillance endoscopy every 1–2 years, depending on the burden of NETs (BPA 10). For gastric NETs ≥1–2 cm, providers should consider endoscopic ultrasound to assess depth of tumor invasion and presence of local metastasis to help guide further management.90 Surgical resection is appropriate for NETs >2 cm, with invasion past the submucosa, or with evidence of lymph node metastasis.89,90
Management of Coexisting Conditions Associated With Atrophic Gastritis

Patients with corpus-predominant AG, irrespective of etiology, are at an increased risk of developing iron and vitamin B-12 deficiency due to reduced gastric acid secretion and intrinsic factor. Iron deficiency is common, with some series reporting this in up to 50% of patients with corpus-predominant AG, and often presents much earlier than the manifestation of B-12 deficiency. Providers should therefore evaluate for iron and vitamin B-12 deficiency in patients with AG, especially if corpus-predominant; likewise, in patients with unexplained iron or vitamin B-12 deficiency, AG should be considered in the differential diagnosis and appropriate diagnostic evaluation pursued (BPA 11).

Providers should recognize that there is an established association between AIG and other autoimmune diseases, especially autoimmune thyroid disease, perhaps related to shared genetic susceptibility loci. Screening for autoimmune thyroid disease should be considered in patients diagnosed with AIG. Providers should also have a low threshold to evaluate for other associated autoimmune diseases, including type 1 diabetes mellitus and Addison’s disease, if the clinical picture is consistent (BPA 12).

Conclusions

Providers should recognize AG as an important, albeit frequently underdiagnosed, condition with both gastric and extragastric manifestations. Patients with severe AG should be considered for endoscopic surveillance for the purpose of early gastric cancer detection and may require additional management considerations, including attention to micronutrient deficiencies, particularly iron and vitamin B-12 deficiencies. Coordinated efforts between gastroenterologists and pathologists are needed to improve the diagnosis and characterization of AG. In addition, collaborative efforts are also needed, particularly in the form of comparative clinical trials in US populations, in order to refine risk stratification algorithms and optimize surveillance strategies for patients with AG.

Supplementary Figure 1. OLGA classification system for risk assessment in AG, which incorporates anatomic extent and histologic grade (A). The OLGA stage is determined by the combination of the histopathologic severity (score 0–3) of atrophic changes in each anatomic compartment (antrum/incisura and corpus). The OLGIM (not pictured) has similar prognostic value for gastric neoplasia as OLGA, with the distinct advantage of improved reproducibility and interobserver agreement, but with the disadvantage of downstaging some high-risk individuals. Stages III and IV in both OLGA and OLGIM systems are associated with a significantly higher risk of gastric cancer compared to stages 0–II. Of note, the Kimura-Takemoto classification (Supplementary Figure 2D, below) demonstrates good correlation with the OLGA system in terms of its value in risk stratification. From Rugge et al, reprinted with permission from Elsevier. (B) Visual analogue scale of the Updated Sydney System for histopathologic severity grading of atrophic changes (right panels). From Dixon et al, reprinted with permission from Wolters Kluwer Health.
**Supplementary Figure 2.** Endoscopic appearance of AG. The characteristic endoscopic features of AG include pale-appearing gastric mucosa, loss of rugal folds, increased visibility of submucosal blood vessels due to the thinning of gastric mucosa, and frequently, presence of a visible atrophic border (A, B). (C, D) Illustrations of the updated Sydney and modified Kimura-Takemoto classification systems for histopathologic and endoscopic staging, respectively, of chronic AG. The numbers in (C) correspond to the topographical locations where biopsies should be obtained: lesser (1) and greater (2) curvatures of the antrum within 2–3 cm of the pylorus; the incisura (3); and lesser (4) and greater (5) curvatures of the corpus. (D) Stomach opened in the coronal view. The Kimura-Takemoto classification categorizes AG as closed (C) or open (O) type, based on the extent of the atrophic border. Closed-type 1 (C-1) atrophy is limited to the antrum, C-2 atrophy is limited to the antrum and lesser curvature of the distal gastric body, and C-3 includes the antrum and lesser curvature of the proximal gastric body, while the atrophic border in open-type (O-1 to O-3) further spreads from the anterior wall (O-1) to the greater curvature (O-3). Multiple reports have shown a strong correlation between the extensive atrophy (O types) and higher risk of gastric cancer compared to limited atrophy (C1-C2 types). The endoscopic image A represents C-2 type with the atrophic border on the lesser curvature between the incisura angularis and cardia, while endoscopic image B represents O-2 type because the atrophic border exists beyond the cardia and in the middle of anterior and posterior walls. | American Gastroenterological Association (AGA), 2020<sup>80</sup> | 1. In patients with GIM, the AGA suggests against routine use of endoscopic surveillance (quality of evidence: very low; grade of recommendation: conditional)  
*Comments*: Patients with GIM at higher risk for gastric cancer who put a high value on potential but uncertain reduction in gastric cancer mortality, and who put a low value on potential risks of surveillance endoscopies, may reasonably elect for surveillance. Patients with GIM specifically at higher risk of gastric cancer include those with: 1) incomplete vs complete GIM; 2) extensive vs limited GIM; and 3) family history of gastric cancer. Patients at overall increased risk for gastric cancer include: 1) racial and ethnic minorities and 2) immigrants from high-incidence regions.  
2. In patients with GIM, the AGA suggests against routine repeat short-interval endoscopy with biopsies for the purpose of risk stratification (quality of evidence: very low; grade of recommendation: conditional)  
*Comments*: Based on shared decision-making, patients with GIM and high-risk stigmata, concerns about completeness of baseline endoscopy, and/or who are at overall increased risk for gastric cancer (ie, racial and ethnic minorities, immigrants from regions with high gastric cancer incidence, or individuals with family history of first-degree relative with gastric cancer) may reasonably elect for repeat endoscopy within 1 y for risk stratification. |
| European Society of Gastrointestinal Endoscopy (ESGE), 2019<sup>38</sup> | 1. For patients with mild to moderate atrophy restricted to the antrum there is no evidence to recommend surveillance (quality of evidence: moderate; grade of recommendation: strong)  
2. Patients with IM at a single location have a higher risk of gastric cancer. However, this increased risk does not justify surveillance in most cases, particularly if a high-quality endoscopy with biopsies has excluded advanced stages of AG (quality of evidence: moderate; grade of recommendation: strong)  
3. In patients with IM at a single location but with a family history of gastric cancer, or with incomplete IM, or with persistent *H pylori* gastritis, endoscopic surveillance with chromoendoscopy and guided biopsies in 3 y may be considered (quality of evidence: low; grade of recommendation: weak)  
4. Patients with advanced stages of AG (severe atrophic changes or IM in both antrum and corpus, OLGA/OLGIM III/IV) should be followed up with a high-quality endoscopy every 3 y (quality of evidence: low; grade of recommendation: strong)  
5. Patients with advanced stages of AG and with a family history of gastric cancer may benefit from a more intensive follow-up (eg, every 1–2 y after diagnosis) (quality of evidence: low; grade of recommendation: weak)  
6. Patients with autoimmune gastritis may benefit from endoscopic follow-up every 3–5 y (quality of evidence: low; grade of recommendation: weak) |
| British Society of Gastroenterology, 2019<sup>39</sup> | 1. Surveillance every 3 y should be offered to patients diagnosed with extensive gastric atrophy or GIM, defined as that affecting the antrum and body (quality of evidence: low quality; grade of recommendation: strong)  
2. Surveillance in patients with gastric atrophy or GIM limited just to the gastric antrum is not recommended, unless there are additional risk factors, such as a strong family history of gastric cancer or persistent *H pylori* infection, then we suggest 3-yearly surveillance (quality of evidence: low; grade of recommendation: strong) |
| Italian Society of Gastroenterology, 2019<sup>5</sup> | 1. Patients with advanced stages of AG, ie, patients with atrophy or IM of at least moderate severity affecting both the antrum and corpus (stage III/IV OLGA or OLGIM) should undergo endoscopic surveillance every 3 y, ideally with high-quality endoscopy (evidence level: C; grade of recommendation: 1)  
2. Patients with AG, in particular when associated with PA, should receive endoscopic surveillance every 3–5 y (evidence level: B; grade of recommendation 2). |

| **American Society of Gastrointestinal Endoscopy (ASGE), 2015**<sup>83</sup> | 1. ASGE suggests surveillance endoscopy for patients with GIM who are at increased risk of gastric cancer due to ethnic background or family history. Optimal surveillance intervals have not been extensively studied and should be individualized (quality of evidence: low; grade of recommendation: not provided)  
2. ASGE suggests endoscopy within 6 mo of the diagnosis of pernicious anemia or the development of upper gastrointestinal symptoms in patients with PA (quality of evidence: low; grade of recommendation: not provided)  
3. ASGE recommends endoscopic ultrasound for local staging of gastric carcinoids (quality of evidence: moderate; grade of recommendation: not provided)  
4. ASGE suggests endoscopic resection of small (<1 cm) type 1 and type 2 gastric carcinoids that do not demonstrate aggressive features, such as angioinvasion, muscular wall invasion, high proliferative index, and or metastatic disease and endoscopic surveillance thereafter every 1–2 y (quality of evidence: low; grade of recommendation: not provided) |
| **Kyoto Global Consensus on Helicobacter pylori Gastritis**<sup>2</sup> | 1. *H pylori* eradication may not completely eliminate the risk of gastric cancer. Patients who remain at risk, as defined by the extent and severity of atrophy, should be offered endoscopic and histologic surveillance (quality of evidence: high; grade of recommendation: strong)  
Comments: Long-term follow-up, such as regular endoscopic surveillance, should be based on estimating the risk of developing gastric cancer after *H pylori* eradication (ie, risk stratification). Cancer risk correlates with the extent and severity of AG and risk stratification should be confirmed using a validated histologic risk scoring systems, such as OLGA or OLGIM. In areas with proven expertise in endoscopic scoring, a system such as that of Kimura and Takemoto can be used initially, although histological confirmation is still recommended. |

**NOTE.** As indicated in the text, providers should recognize that a diagnosis of IM almost invariably implies underlying AG. Accordingly, guidelines on IM management are included. Recommendations on surveillance of dysplasia are not included and are beyond the scope of this Clinical Practice Update.
